ABSTRACT

Objectives: The purposes of the present study were 1) to systematically review the literature on the surgical non-regenerative treatments of peri-implantitis and 2) to determine a predictable therapeutic option for the clinical management of peri-implantitis lesions.

Material and Methods: The study search was performed on primary database MEDLINE and EMBASE from 2005 until 2016. Sequential screenings at the title, abstract, and full-text levels were performed. Clinical human studies in the English language that had reported changes in probing depth (PD) and/or bleeding on probing (BOP) and/or radiologic marginal bone level changes after peri-implantitis surgical non-regenerative treatment at 6-month follow-up or longer were included accordingly PRISMA guidelines.

Results: The first electronic and hand search resulted in 765 citations. From 16 full-text articles reviewed, 6 were included in this systematic review. Surgical non-regenerative methods were found to be efficient in reducing clinical parameters. BOP and PD values were significantly decreased following implantoplasty and systematic administration of antibacterials, but not after local application of chemical compounds or diode laser. Similarly, significant improvement in clinical and radiographic parameters was found only after implantoplasty compared with resective surgery alone. We found significant heterogeneity in study designs and treatments provided among the pooled studies. All of the studies revealed an unclear or high risk of bias.

Conclusions: Surgical non-regenerative treatment of peri-implantitis was found to be effective to reduce the soft tissue inflammation and decrease probing depth. More randomized controlled clinical trials are needed to assess the efficacy of surgical non-regenerative therapy of peri-implantitis.

Keywords: alveolar bone loss; oral surgery; nonsurgical periodontal debridement; peri-implantitis; review.

INTRODUCTION

Over the last decades, the use of dental implants has become a standard treatment option to replace missing or hopeless teeth. Several longitudinal studies have reported high survival rates for implants placed, over a period of 10 years [1,2]. Despite of these encouraging data for the use of dental implants in oral rehabilitation, clinicians shall consider several types of complications that may be encountered. Plaque-induced peri-implantitis is considered one of the most common biological complication [3]. Peri-implantitis can be defined as a clinical condition characterized by an inflammatory reaction that involves the hard and soft tissue, with pathological pocket formation and loss of supporting bone around osseointegrated dental implants [4,5].

Bacteria accumulation on the implant surface plays an important role in the aetiology of peri-implantitis [6]. The microorganisms essential for the development of infections around dental implants seems similar to the bacteria that cause periodontal diseases. However, recent data pointed to the presence of also very specific microorganisms [7]. The sub marginal plaque contains a large variety of Gram-negative anaerobic rods, fusiform bacteria, motile and curved rods as well as spirochetes [8] and large amounts of densely packed inflammatory cells that frequently accompanied by a crater-like bone defect surrounding the implant [9,10]. The treatment of peri-implantitis thus aims to arrest the progression of the disease by an anti-inflammatory therapy in order to prevent the progressive loss of supporting bone. Thereafter, peri-implant tissues can be re-established and the healthy soft and hard tissues maintained [11]. Actually, many endosseous implants may be successfully used as prosthetic abutments in fully and partially edentulous patients for a prolonged period of time [5]. Nevertheless, numerous aetiological factors may play a decisive role for the progress of infection. The micro and macro design of the implant, the abutment connection, the passive adjustment of the prosthesis and the excessive mechanical load are all related with the disease [12].

Several clinical protocols for treatment of peri-implantitis have been proposed, including mechanical debridement, the use of antiseptics and local or systemic antibiotics [13-15], surgical access [16,17], and regenerative [18-20] or resective surgical procedures [21-23]. However, the currently available evidence does not provide any firm or specific recommendations for the surgical therapy of peri-implantitis [24]. A recent meta-analyses confirmed

that it's possible to obtain a significant reduction in radiological peri-implant marginal bone level using either treatment approaches [25]. The treatment of peri-implant bone loss is thus quite challenging for the clinician.

The purpose of this review is to screen the recent literature on surgical non-regenerative treatment of peri-implantitis. The effectiveness of various surgical non-regenerative treatment modalities was evaluated in relation to the resolution of different clinical and radiographic parameters. Accordingly, this review may help clinicians in the selection of the most appropriate surgical non-regenerative treatment modality.

MATERIAL AND METHODS

Protocol and registration

The review was registered in PROSPERO, an international prospective register of systematic reviews under number CRD42016043320. The methods of the analysis and inclusion criteria were specified in advance and documented in a protocol, accessible through the following link:

http://www.crd.york.ac.uk/PROSPERO/display_record.asp?ID=CRD42016043320

The reporting of this systematic analysis adhered to the Preferred Reporting Items for Systematic Review and Meta-Analyses (PRISMA) statement [26].

Focus question

The following focus question was developed according to the population, intervention, comparison, and outcome (PICO) study design: what are the overall treatment outcomes of surgical non-regenerative procedures applied in the treatment of peri-implantitis lesions?

Types of publications

The review included clinical studies in humans published in English language. Letters, editorials, case reports, literature reviews, and PhD theses were excluded.

Types of studies

The review included all human prospective and retrospective studies and clinical trials, cohort studies, case-control studies, and case series studies published between January 2005 and January 2016, on surgical non-regenerative treatment of peri-implantitis.

Information sources

The search strategy for relevant studies comprised the evaluation of electronic databases including Ovid MEDLINE, PubMed, EMBASE and Dentistry and Oral Sciences Source published in the English language. A supplementary hand search of the reference lists performed in dental and implant-related journals limited to English language was carried out to source additional relevant publications for the same time period in following journals: 1) “Journal of Periodontology”; 2) “Clinical Implant Dentistry and Related Research”; 3) “International Journal of Oral and Maxillofacial Implants”; 4) “Clinical Oral Implants Research”; 5) “Implant Dentistry”; 6) “International Journal of Oral and Maxillofacial Surgery”; 7) “Journal of Oral and Maxillofacial Surgery”; 8) “Journal of Dental Research”; 9) “Journal of Prosthetic Dentistry”; 10) “International Journal of Prosthodontics”; 11) “Journal of Oral Implantology”; 12) “Journal of Clinical Periodontology”; 13) “International Journal of Periodontics & Restorative Dentistry”; 14) “European Journal of Oral Implantology”.

Search

The keywords used in the search of the selected electronic databases included the following: “peri-implantitis” OR “periimplantitis” OR “peri-implant” OR “periimplant” or (“implant” AND “failure”) AND “surgical” OR “treatment” OR “therapy” OR “non-regenerative” OR “nonregenerative” OR “laser” OR “lasers”. The choice of keywords was intended to be extensive to collect as much relevant data as possible and to refine the search results, without relying on electronic means alone.

Selection of studies

The resulting articles were revised by two independent reviewers to ascertain the inclusion and exclusion criteria, compare their decisions and resolve possible differences through discussion. An experienced senior reviewer was consulted when consensus could not be reached. The level of agreement between the reviewers regarding study inclusion was calculated using κ statistics. At the title and abstract stage, one reviewer accepted the citations that appeared to meet inclusion criteria and send them to full-text review, with a second reviewer assessing only those citations and abstracts that the first reviewer deemed ineligible. Consequently, a complete independent dual review of full-text articles was undertaken.

Disease definition

The authors of this review classified peri-implantitis in all cases where there was a clear radiographic threshold > 2 mm of continuous marginal bone loss beyond biologic peri-implant bone remodelling, presence of bleeding on probing (BOP) and/or suppuration on probing with probing depth (PD) more than 6 mm [3].

Inclusion and exclusion criteria

The full text of all studies of possible relevance was obtained for assessment against the following inclusion criteria:

- Investigated surgical non-regenerative treatment in patients with at least one osseointegrated screw-shaped dental implant, that presented signs of peri-implantitis;
- Studies involving at least one surgical non-regenerative treatment method of peri-implantitis;
- All human prospective or retrospective follow-up studies and clinical trials, cohort studies, case-control studies, and case series studies with a minimal sample size of 10 implants and a minimum 6 months of follow-up period;
- Report on clinical and radiographic peri-implant tissues changes, including PD and/or BOP as primary outcome measure and/or radiographic bone level (RBL) change as secondary outcome measure.

The applied exclusion criteria for studies were as follows:

- *In vitro* and *in vivo* studies;
- Studies involving patients with specific systemic diseases, immunologic disorders, uncontrolled diabetes mellitus, osteoporosis, or other implant risk related systemic conditions;
- Studies investigating ceramic or coated implants surface;
- Insufficient information regarding the selected topic;
- Non accessible relevant data, such as impossibility to contact the authors for any reason.

Sequential search strategy

All article titles were screened to eliminate irrelevant publications considering the exclusion criteria. Next, some studies were excluded based on data obtained after reading the abstracts. At the final stage, the full texts were screened based on the inclusion criteria to confirm the eligibility of each study.

Data extraction

The data were extracted and collected from included studies in the form of variables. According to the aim of the present review, the data were arranged as follows:

- “Author (Year)” - revealed the author and year of publication.
- “Type of study” - indicated the type of the study.
- “Sample size” - described the number of patients examined.
- “Detoxification method” - described additional implant surface detoxification measures applied in addition to the instrumental debridement and degranulation.
- “Antimicrobial” - described antimicrobial agents (e.g. systemic antibiotics, chlorhexidine mouth rinse) used adjunctive to the surgery.
- “Probing depth change (Δ PD)” - described PD difference (in mm) before and after surgical treatment.
- “Bleeding on probing change (Δ BOP)” - described BOP difference (in %) before and after surgical treatment.
- “Radiologic bone level change (Δ RBL)” - described the marginal bone level difference (in mm; measured from implant shoulder to the bone surface) before and after the treatment; and/or intrabony defect depth difference (in mm; measured from the bottom of the defect to the interproximal bone) before and after treatment.
- “Follow-up” - described the duration of the observed outcomes.

Risk of bias assessment

The risk of bias was assessed independently and in duplicate by the two authors during the data extraction process, using the Cochrane Collaboration’s two-part tool for assessing risk of bias [27]. The following possible sources of bias were addressed: random sequence generation (selection bias); allocation concealment (selection bias); blinding of participants and personnel (performance bias and detection bias); incomplete outcome data (attrition bias); selective reporting (reporting bias) and other bias (examiner blinding, examiner calibration, standardized probing force, and standardized radiographic assessment). The authors’ judgment for each source of bias item was assigned for each study in the data extraction table (Table 1). An overall risk of bias was then assigned to each trial according to Higgins et al. [27]. The degrees of bias were categorized as: (1) low risk, if all the

criteria were met; (2) moderate risk, when only one criterion was missing; (3) high risk, if two or more criteria were missing and (4) unclear risk, if too few details were available to make a judgement of certain risk assessment.

RESULTS

Study selection

Article review and data extraction were performed according to the PRISMA flow diagram (Figure 1). The initial search displayed 765 results from the MEDLINE (NCBI PubMed and PMC) and EMBASE databases and 3 results from other sources. A total of 768 search results were initially screened. The inclusion and exclusion criteria were applied to 16 full-text articles.

The κ value for inter-reviewer agreement for potentially relevant articles was 1 (titles and abstracts) and > 0.9 (full-text articles), indicating a “very good” agreement between the 2 reviewers, according to the criteria of Landis and Koch [28].

Study exclusion

Ten studies were excluded after full-text assessment, being a review paper ($n = 7$) and due to methodological and design faults ($n = 3$).

Study characteristics

Finally, 6 articles were included in the review [16,17,21-23,29]. The summarized individual study characteristics are described in Table 2. A total of 150 patients diagnosed with peri-implantitis were treated in the included studies using different surgical non-regenerative methods.

From the included studies, two were prospective randomized controlled trials [17,22,23], one was prospective cohort study [16] and two were retrospective controlled studies [21,29]. One study included a follow-up period of 6 months [17], three of 1 year [16,21,29] and two up to 3 years [22,23]. The mean reported age of the patients ranged from 55 [17] to 61.5 years [21].

All studies included rough surface dental implants. A total of 14 implants treated with respective surgery were lost [21,29]. Due to the persisting inflammation, 15 implants had to be removed following resective surgery [21-23]. One implant was removed due to the fracture of the implant neck [29].

Four studies reported on smoking status of the patients, ranging from 25% [16] to 59.1% [29].

Table 1. Descriptive information of the included studies

Study	Year of publication	Type of study	Implant surface	Treatment method used	Sample size	Smokers	Follow-up (months)	PD changes Mean (SD)	BOP changes Mean (SD)	Radiographic marginal bone level changes/ bone defect fill	Comments
Heitz-Mayfield et al. [16]	2012	Prospective cohort study	36 implants, rough	Open flap debridement and implant surface decontamination with saline and with adjunctive systemic amoxicillin and metronidazole	24 patients; mean age 56	0.25	12	Baseline: mean PD \geq 6 mm: 20%; $5 \leq$ PD < 6 mm: 25%; $4 \leq$ PD < 5 mm: 28%; < 4 mm: 7%. After 12 months: \geq 6 mm: 0%; $5 \leq$ PD < 6 mm: 0%; $4 \leq$ PD < 5 mm: 11%; < 4 mm: 89%. Statistically significant ($P < 0.01$) reduction in mean PD.	Number of sites with BOP: - baseline: 2.5 (1); - after 12 months: 1 (1.2). Statistically significant ($P < 0.01$) reduction in BOP.	Three implants in 3 patients had 0.6 - 1 mm bone loss at 12 months. Three implants in 3 patients showed bone gain, while the remaining implants had stable marginal bone levels.	Access flap surgery in combination with systemic antibiotics was an effective treatment resulting in significantly reduced BOP and PD scores.
Papadopoulos et al. [17]	2015	Randomized controlled clinical study	Not known	Group 1: open flap debridement alone. Group 2: open flap debridement with the additional use of a diode laser for the treatment of peri-implantitis.	16: age 55. (40 - 73) Group 1: 8 Group 2: 8	Not known	6	Group 1: - baseline mean PD 5.92 mm; - after 6 months 4.44 mm; - reduction of 1.38 mm. Group 2: - baseline mean PD 5.52 mm; - after 6 months 4.31 mm; - reduction of 1.19 mm. No statistically significant difference between the 2 groups.	Group 1: - baseline 93.5%; - after 6 months 31.3%; - mean reduction 72.9%. Group 2: - baseline 81.2%; - after 6 months 23.8%; - mean reduction 66.7% ($P < 0.05$). No statistically significant difference between groups.		Surgical treatment of peri-implantitis by access flap surgery resulted in improvement of clinical parameters. The additional use of a diode laser did not have any extra beneficial effect.
de Waal et al. [21]	2013	Retrospective clinical study	79 implants, rough	Resective surgery with bone recontouring and surface decontamination. Group 1: 0.12% CHX + 0.05% CPC. Group 2: placebo.	30: Group 1: 15 age 61.5 Group 2: 15 age 59.4	46.7	12	Mean PD \geq 5 mm: Group 1: - baseline 88.2 (18.4%); - after 12 months 733.9 (39)%. Group 2: - baseline 75.2 (26.1%); - after 12 months 17.1 (24)% Mean PD \geq 6 mm: Group 1: - baseline 54.5 (33.7%); - after 12 months 17.7 (34.3)%. Group 2: - baseline 46.9 (33.7%); - after 12 months 17.2 (19.2)%.	Group 1: - baseline 87.1 (27%); - after 12 months 25.8 (8)%. Group 2: - baseline 81.3 (39%); - after 12 months 15.8 (6)%.	Mean MBL: Group 1: - baseline 4.3 (2.1) mm; - after 12 months 5 (2.5) mm. Group 2: - baseline 3.61 (1.9) mm; - after 12 months 3.9 (2) mm.	Improved clinical parameters (eg, BOP and PD) and MBL compared with the baseline were observed in both groups, with no significant difference between them.
Romeo et al. [22]	2005	Randomized clinical study	35 implants, rough	Group 1 (test): resective surgery and modification of surface topography (implantoplasty). Group 2: resective surgery only (control group).	17: Group 1: 10 Group 2: 7	29	36	Group 1: - baseline 5.79 (1.69) mm; - after 36 months 3.21 (0.56) mm (Student's t-value of +11.63). Group 2: - baseline 6.52 (1.62) mm; - after 24 months 5.5 (1.47) mm (Student's t-value of +3.18).	Mean bleeding index: Group 1: - baseline 2.83 (0.47); - after 36 months 0.61 (0.67) (Student's t-value of +16.02). Group 2: - baseline 2.86 (0.35); - after 24 months 2.33 (0.75) (Student's t-value of +3.33).		Clinical parameters improved in both treatment groups, without a significant difference between them.
Romeo et al. [23]	2007	Randomized clinical study	38 implants, rough	Group 1 (test): resective surgery and implantoplasty. Group 2 (control): resective surgery alone.	19: Group 1: 10 Group 2: 9	Not reported	36			Group 1: - baseline mesially 3.82 (1.52) mm, distally 3.94 (1.64) mm; - after 3 years mesially 3.81 (3.94) mm, distally 1.72 (1.79) mm. Group 2: - baseline mesially 3.45 (1.93) mm, distally 3.49 (1.8) mm; - after 3 years mesially 5.35 (1.99) mm, distally 5.42 (1.91) mm Significantly higher ($P < 0.05$) mean MBL was recorded in group 2 than in group 1.	A significantly extended MBL was reported in the group without implantoplasty.
de Waal et al. [29]	2015	Retrospective clinical study	108 implants, rough	Resective surgery with bone recontouring and surface decontamination. Group 1: 0.2% chlorhexidine solution. Group 2: 0.12% CHX + 0.05% CPC.	44: Group 1: 22 age 60.5 Group 2: 22 age 58.6	59.1	12	Mean PD \geq 5 mm: Group 1: - baseline 57.5 (26.6%); - after 12 months 7.3 (12.6)%. Group 2: - baseline 60.2 (28.3%); - after 12 months 5.3 (12.5)%. Mean PD \geq 6 mm: Group 1: - baseline 29.1 (31.6%); - after 12 months 2.1 (7)%. Group 2: - baseline 34.4 (31.8%); - after 12 months 1.4 (5.8)%. No significant difference between the groups ($P = 0.6$).	Group 1: - baseline 82.1 (23.9%); - after 12 months 42.7 (34.2)%. Group 2: - baseline 74.2 (27.8%); - after 12 months 37.0 (35.3)%. No significant difference between the groups ($P = 0.6$).	Mean MBL: Group 1: - baseline 4 (1.5) mm; - after 12 months 4.3 (1.7) mm. Group 2: - baseline 4.1 (1.6) mm; - after 12 months 4.1 (1.7) mm. Radiologic bone loss was not significantly different between the groups ($P = 0.8$).	Improved clinical parameters (e.g. BOP and PD) and MBL compared with the baseline were observed in both groups, with no significant difference between them.

CPC = Cetylpyridinium chloride; CHX = chlorhexidine; MBL = marginal bone loss; PD = probing depth; BOP = bleeding on probing.

Figure 1. PRISMA flow diagram.

Table 2. Assessment of the risk of bias

Author	Random sequence generation	Allocation concealment	Blinding	Incomplete outcome data	Selective reporting	Other bias
Heitz-Mayfield et al. [16]	?	?	?	-	-	-
Papadopoulos et al. [17]	+	?	+	+	?	+
de Waal et al [21]	+	+	+	+	-	+
Romeo et al. [22]	-	-	-	+	-	+
Romeo et al. [23]	-	-	-	+	-	+
de Waal et al. [29]	+	+	+	+	-	+

+ = low risk; ? = unclear risk; - = high risk.

The study of Heitz-Mayfield et al. [16] showed no negative effect of smoking on treatment outcome. Smoking was, however, relevant for treatment success when for the crude model adjusted for the baseline and time, but not when adjusted for baseline, time smoking, dental status, history of periodontitis and implant surface roughness [21,29].

An improvement in peri-implant clinical parameters was found in four studies using access flap surgery only [17,21-23], surface decontamination with chlorhexidine (CHX) and/or cetylpyridinium chloride (CPC) [21,29] and systemic antibiotics [16]. Significant decrease in BOP scores was showed in studies reporting implantoplasty [22] or use of systemic antimicrobials [16], but not by using CHX with CPC [21,29] or diode laser [17]. Similarly, a significant improvement in PD scores resulted with the addition of implantoplasty [22] or systemic antimicrobials [16], but did not by using the CHX with CPC [21,29] or the diode laser [17].

Initial radiologic bone defect depth was measured in four studies; in three studies the distance was measured from the implant shoulder to the first bone contact [21,23,29] or using landmarks as the threads of the implants [16]. The mean peri-implant bone level at basement ranged from 3.45 mm [23] to 4.1 mm [29]. Stable peri-implant bone level was found following systemic application of antibiotics [16] or local use of chemical compounds [21,29].

The addition of chemical compounds [21,29] or diode laser [17] showed no difference in clinical parameters compared to mechanical debridement. On the other hand, implantoplasty demonstrated significant improvement in clinical and radiographic parameters compared to mechanical debridement alone [22,23].

Risk of bias across studies

Summarizing the risk of bias for each study, 4 studies were classified as unclear risk (of bias for 1 or more key domains) [16,17,23] and two studies were judged to have a high risk (of bias for more than 1 domain) [21,22]. The risk of bias assessment for the included studies is summarized in Table 1.

DISCUSSION

Present review aimed to assess the overall treatment outcome of surgical non-regenerative procedures applied in the treatment of peri-implantitis lesions. The surgical non-regenerative treatment is a relatively simple procedure, but it depends on various multiple factors including patient general health condition,

oral hygiene habits, defect configuration, implant surface characteristics, decontamination procedure, postoperative maintenance program, and various other factors that are not possible to fit within the frames of systematic literature review and meta-analysis. Hereby, we included studies reporting the clinical and/or radiological outcomes of different surgical non-regenerative treatment methods. Our findings suggest that the effectiveness of peri-implantitis treatment using different surgical non-regenerative modalities is restrained. Reduction of signs of inflammation (decreased BOP index and reduced PD) could be expected and the arrest of continuous bone loss may be expected.

Present findings resemble the statement of the Third European Association for Osseointegration Consensus Conference [30], which claims that peri-implantitis respond well to the surgical non-regenerative treatment, whereas the mechanical debridement alone has limited efficacy. Carbon fiber and/or titanium curettes for debridement are recommended as they cause minimal damage to implant surfaces [31], but the decontamination of the implant surface is considered mandatory for the successful treatment. Different methods were suggested including chemical, mechanical and laser decontaminations [32], aiming the elimination of bacteria and the creation of an implant surface favourable to bone regeneration and re-osseointegration [33]. According to the *in vitro* study, airflow devices using glycine powders were shown to constitute an efficient therapeutic option for the debridement of implants in peri-implantitis defects [34]. However, we didn't found any study related with the use of airflow devices in surgical non-regenerative surgery. Combined mechanical and chemical removal of biofilm from the implant surface is further recommended [32]. Chlorhexidine digluconate (0.2%) and ethylenediaminetetraacetic acid (24%) demonstrated a considerable decontamination capacity with respect to killing as well to the removal of biofilm cells [35]. The results of the present review indicate that the surface decontamination/debridement using chlorhexidine digluconate reduce bacterial count without significant improvement of the clinical parameters [29]. Furthermore, the suppression of anaerobic bacteria did not lead to better clinical and radiographic outcomes [21].

The majority of surgical protocols include pre-operative or postoperative systemic antibiotics followed by postoperative chlorhexidine rinse. The systematic administration of antimicrobials in the study of Heitz-Mayfield et al. [16] contributed in reducing BOP and PD by surface decontamination following open flap debridement.

Wohlfahrt et al. [36] prescribed systemic antibiotics 3 days prior and 7 days after open flap surgery, mechanical debridement, decontamination and placement of the porous titanium granules. Both treatments provided significant clinical improvements in PD, but the reconstruction with porous titanium granules resulted in better radiographic peri-implant defect correction. In a recent review, Van Winkelhoff [15] found that there is still a need for randomized clinical trials on the systematic use of antibiotics. Local antibiotic delivery in addition to mechanical debridement and irrigation with an antimicrobial agent may be effective option for treating peri-implantitis lesions [13]. Furthermore, the development of bacterial resistance seems to be very unlikely even in the event of repeated applications [37].

The results of Romeo et al. [23] have demonstrated the advantage of implantoplasty compared to the resective surgery alone in terms of marginal bone preservation in cases with advanced peri-implantitis. The implantoplasty was later applied by comparison of Er:YAG laser and saline for implant surface decontamination during combined resective/regenerative surgery; both decontamination methods resulted in significant reduction of BOP and clinical attachment level [20]. Subsequently, positive effects of implantoplasty without implant surface decontamination were confirmed by clinical and radiographic parameters using similar treatment approach [18].

According to the results of this review, the surgical treatment approach should be a treatment option in cases of evident bone loss and pocket formation over 5 mm. Nevertheless, it is evident that successful peri-implant lesion treatment is a comprehensive procedure. The progression of peri-implantitis resistant to the treatment may result in implant mobility. In such cases, the removal of the implant with a successive regenerative procedure is the only therapeutic option [18-23]. As the majority of the studies reporting on regenerative surgical treatments demonstrated significant improvement in clinical parameters and intrabony defect fill, one might suppose that a regenerative approach should be the treatment of choice. Yet, more recently Khoshkam et al. [38] stated a lack of evidence to support the additional benefit of reconstructive therapy as compared to non-reconstructive procedures.

Oral hygiene instructions and the importance of plaque control must be stressed to patients before and after the treatment [39]. Nonsurgical subgingival mechanical debridement in conjunction with local antibacterials, like chlorhexidine digluconate or

locally delivered antibiotics are effective in reducing soft-tissue inflammation [14,40,41] and should be the first step in successful treatment. After soft tissue health has been achieved and patient's oral hygiene improved, the treatment could be continued with the surgical step. The supportive treatment phase, by oral hygienists following surgery is an imperative as the last step for the success of peri-implantitis treatment [20,21]. Serino et al. [42] demonstrated that in patients with a high standard of oral hygiene and enrolled in a recall system every 6 months, the peri-implant conditions obtained following peri-implant surgery were maintained stable, for the majority of subjects and implants, during a 5-year period.

Limitations

The evidence of this systematic review was limited to randomized, controlled clinical studies. The revised studies were relatively of short follow-up period and included relatively small numbers of patients. The absence of a control group (without treatment or placebo) was also a limitation. Finally, there were various degrees of heterogeneity in the study design and treatment provided among the pooled studies.

All of the studies included in this review revealed an unclear or high risk of bias. The proportion of information from studies with unclear or high risk of bias may be sufficient to affect the interpretation of results [27]. However, the strength of evidence of this review is low due to the significant variations observed in the included studies.

CONCLUSIONS

The present systematic review revealed that peri-implantitis treatments using different surgical non-regenerative modalities are of limited effectiveness. It can be concluded that the use of implantoplasty or systemic antimicrobials in surgical non-regenerative treatment of peri-implantitis lead to a significant decrease in bleeding on probing and probing depth. Furthermore, the application of chemical compounds or diode laser did not result in significant clinical or radiographic alterations. Implantoplasty may result in improvement in clinical and radiographic parameters compared to mechanical debridement alone. There is limited evidence that a peri-implant bone level may be arrested. Further clinical studies should be conducted for the assessment of complex management and the efficacy of the maintenance protocol.
